## Vce PCEP-30-02 Test Simulator - Pass Guaranteed 2026 First-grade Python Institute PCEP-30-02 Answers Real Questions

Every candidate wants to pass the PCEP-30-02 exam in the least time successfully. More importantly, it is necessary for these people to choose the convenient and helpful PCEP-30-02 test questions as their study tool in the next time. Because their time is not enough to prepare for the PCEP-30-02 exam, and a lot of people have difficulty in preparing for the exam, so many people who want to pass the PCEP-30-02 Exam and get the related certification in a short time are willing to pay more attention to our PCEP-30-02 study materials as the pass rate is high as 99% to 100%.

### Python Institute PCEP - Certified Entry-Level Python Programmer Sample Questions (Q23-Q28):

#### NEW QUESTION # 23

Which of the following functions can be invoked with two arguments?

- A.
- B.
- C.
- D.

#### Answer: C

##### Explanation:

The code snippets that you have sent are defining four different functions in Python. A function is a block of code that performs a specific task and can be reused in the program. A function can take zero or more arguments, which are values that are passed to the function when it is called. A function can also return a value or None, which is the default return value in Python.

To define a function in Python, you use the def keyword, followed by the name of the function and parentheses. Inside the parentheses, you can specify the names of the parameters that the function will accept.

After the parentheses, you use a colon and then indent the code block that contains the statements of the function. For example: def function\_name(parameter1, parameter2): # statements of the function return value To call a function in Python, you use the name of the function followed by parentheses. Inside the parentheses, you can pass the values for the arguments that the function expects. The number and order of the arguments must match the number and order of the parameters in the function definition, unless you use keyword arguments or default values. For example:

function\_name(argument1, argument2)

The code snippets that you have sent are as follows:

- A) def my\_function(): print("Hello")
- B) def my\_function(a, b): return a + b
- C) def my\_function(a, b, c): return a \* b \* c
- D) def my\_function(a, b=0): return a - b

The question is asking which of these functions can be invoked with two arguments. This means that the function must have two parameters in its definition, or one parameter with a default value and one without.

The default value is a value that is assigned to a parameter if no argument is given for it when the function is called. For example, in option D, the parameter b has a default value of 0, so the function can be called with one or two arguments.

The only option that meets this criterion is option B. The function in option B has two parameters, a and b, and returns the sum of them. This function can be invoked with two arguments, such as my\_function(2, 3), which will return 5.

The other options cannot be invoked with two arguments. Option A has no parameters, so it can only be called with no arguments, such as my\_function(), which will print "Hello". Option C has three parameters, a, b, and c, and returns the product of them. This function can only be called with three arguments, such as my\_function(2, 3, 4), which will return 24. Option D has one parameter

with a default value, b, and one without, a, and returns the difference of them. This function can be called with one or two arguments, such as `my_function(2)` or `my_function(2, 3)`, which will return 2 or -1, respectively. Therefore, the correct answer is B. Option B.

#### NEW QUESTION # 24

What is true about exceptions and debugging? (Select two answers.)

- A. A tool that allows you to precisely trace program execution is called a debugger.
- B. If some Python code is executed without errors, this proves that there are no errors in it.
- C. One try-except block may contain more than one except branch.
- D. The default (anonymous) except branch cannot be the last branch in the try-except block.

**Answer: A,C**

Explanation:

Explanation

Exceptions and debugging are two important concepts in Python programming that are related to handling and preventing errors.

Exceptions are errors that occur when the code cannot be executed properly, such as syntax errors, type errors, index errors, etc.

Debugging is the process of finding and fixing errors in the code, using various tools and techniques. Some of the facts about exceptions and debugging are:

A tool that allows you to precisely trace program execution is called a debugger. A debugger is a program that can run another program step by step, inspect the values of variables, set breakpoints, evaluate expressions, etc. A debugger can help you find the source and cause of an error, and test possible solutions. Python has a built-in debugger module called `pdb`, which can be used from the command line or within the code. There are also other third-party debuggers available for Python, such as PyCharm, Visual Studio Code, etc.<sup>12</sup> If some Python code is executed without errors, this does not prove that there are no errors in it. It only means that the code did not encounter any exceptions that would stop the execution. However, the code may still have logical errors, which are errors that cause the code to produce incorrect or unexpected results. For example, if you write a function that is supposed to calculate the area of a circle, but you use the wrong formula, the code may run without errors, but it will give you the wrong answer. Logical errors are harder to detect and debug than syntax or runtime errors, because they do not generate any error messages. You have to test the code with different inputs and outputs, and compare them with the expected results.<sup>34</sup> One try-except block may contain more than one except branch. A try-except block is a way of handling exceptions in Python, by using the keywords `try` and `except`. The `try` block contains the code that may raise an exception, and the `except` block contains the code that will execute if an exception occurs. You can have multiple `except` blocks for different types of exceptions, or for different actions to take. For example, you can write a try-except block like this:

```
try: # some code that may raise an exception
except ValueError: # handle the ValueError exception
except ZeroDivisionError: # handle the ZeroDivisionError exception
except: # handle any other exception
    This way, you can customize the error handling for different situations, and provide more informative messages or alternative solutions.5 The default (anonymous) except branch can be the last branch in the try-except block. The default except branch is the one that does not specify any exception type, and it will catch any exception that is not handled by the previous except branches. The default except branch can be the last branch in the try-except block, but it cannot be the first or the only branch. For example, you can write a try-except block like this:
```

```
try: # some code that may raise an exception
except ValueError: # handle the ValueError exception
except: # handle any other exception
    This is a valid try-except block, and the default except branch will be the last branch. However, you cannot write a try-except block like this:
```

```
try: # some code that may raise an exception
except: # handle any exception
    This is an invalid try-except block, because the default except branch is the only branch, and it will catch all exceptions, even those that are not errors, such as KeyboardInterrupt or SystemExit. This is considered a bad practice, because it may hide or ignore important exceptions that should be handled differently or propagated further. Therefore, you should always specify the exception types that you want to handle, and use the default except branch only as a last resort.5 Therefore, the correct answers are A. A tool that allows you to precisely trace program execution is called a debugger. and C. One try-except block may contain more than one except branch.
```

#### NEW QUESTION # 25

Python is an example of which programming language category?

- A. machine
- B. compiled
- C. interpreted
- D. assembly

**Answer: C**

Explanation:

Explanation

Python is an interpreted programming language, which means that the source code is translated into executable code by an interpreter at runtime, rather than by a compiler beforehand. Interpreted languages are more flexible and portable than compiled languages, but they are also slower and less efficient. Assembly and machine languages are low-level languages that are directly executed by the hardware, while compiled languages are high-level languages that are translated into machine code by a compiler before execution.

### NEW QUESTION # 26

Arrange the code boxes in the correct positions to form a conditional instruction which guarantees that a certain statement is executed when the temperature variable is equal to 0. 0.

□ **Answer:**

Explanation:

if temperature == 0.0:

Explanation:

\* if

\* temperature

\* ==

\* 0.0

\* :

Arrange the boxes in this order:

This checks if temperature is exactly 0.0, and if so, runs the code inside the if block.

### NEW QUESTION # 27

Arrange the binary numeric operators in the order which reflects their priorities, where the top-most position has the highest priority and the bottom-most position has the lowest priority.

□

□ **Answer:**

Explanation:

□ Explanation:

The correct order of the binary numeric operators in Python according to their priorities is:

\* Exponentiation (\*\*)

\* Multiplication (\*) and Division (/, //, %)

\* Addition (+) and Subtraction (-)

This order follows the standard mathematical convention of operator precedence, which can be remembered by the acronym PEMDAS (Parentheses, Exponents, Multiplication/Division, Addition/Subtraction).

Operators with higher precedence are evaluated before those with lower precedence, but operators with the same precedence are evaluated from left to right. Parentheses can be used to change the order of evaluation by grouping expressions.

For example, in the expression  $2 + 3 * 4 ** 2$ , the exponentiation operator (\*\*) has the highest priority, so it is evaluated first, resulting in  $2 + 3 * 16$ . Then, the multiplication operator (\*) has the next highest priority, so it is evaluated next, resulting in  $2 + 48$ . Finally, the addition operator (+) has the lowest priority, so it is evaluated last, resulting in 50.

You can find more information about the operator precedence in Python in the following references:

### NEW QUESTION # 28

.....

Many students often start to study as the exam is approaching. Time is very valuable to these students, and for them, one extra hour of study may mean 3 points more on the test score. If you are one of these students, then PCEP - Certified Entry-Level Python Programmer exam tests are your best choice. Because students often purchase materials from the Internet, there is a problem that

they need transport time, especially for those students who live in remote areas. When the materials arrive, they may just have a little time to read them before the exam. However, with PCEP-30-02 Exam Questions, you will never encounter such problems, because our materials are distributed to customers through emails.
